

Clinical Pharmacogenetics Implementation Consortium Guideline for *CYP2D6* and *CYP2C19* Genotypes and Dosing of Tricyclic Antidepressants

JK Hicks¹, JJ Swen², CF Thorn³, K Sangkuhl³, ED Kharasch⁴, VL Ellingrod^{5,6}, TC Skaar⁷, DJ Müller⁸, A Gaedigk⁹ and JC Stingl¹⁰

Polymorphisms in *CYP2D6* and *CYP2C19* affect the efficacy and safety of tricyclics, with some drugs being affected by *CYP2D6* only, and others by both polymorphic enzymes. Amitriptyline, clomipramine, doxepin, imipramine, and trimipramine are demethylated by *CYP2C19* to pharmacologically active metabolites. These drugs and their metabolites, along with desipramine and nortriptyline, undergo hydroxylation by *CYP2D6* to less active metabolites. Evidence from published literature is presented for *CYP2D6* and *CYP2C19* genotype-directed dosing of tricyclic antidepressants.

The use of tricyclics to treat psychological disorders has declined in part because of the occurrence of undesirable side effects. Although tricyclics are still used to treat depression,¹ their main therapeutic use is often for pain management.^{2,3} Interindividual differences in side effects and treatment response have been associated with variability of tricyclic plasma concentrations.^{4,5} Because both enzymes influence plasma concentrations, the effectiveness and tolerability of tricyclics are affected by *CYP2D6* metabolism and partially by *CYP2C19* metabolism.⁴ The purpose of this guideline is to provide information regarding how to use existing *CYP2D6* and/or *CYP2C19* genotyping test results to guide dosing of tricyclics for psychological disorders and pain management, focusing particularly on amitriptyline and nortriptyline.

Optimal therapeutic plasma concentrations for the tricyclics have been defined.⁶ Poor or ultrarapid metabolizers of *CYP2D6*

and *CYP2C19* may have tricyclic plasma concentrations outside the recommended therapeutic range, thereby increasing the risk of treatment failure or side effects.^{7–10} Therefore, this guideline takes into consideration both clinical outcomes and observed tricyclic plasma concentrations based on genotype/phenotype characteristics. Detailed guidelines for use of other laboratory tests including therapeutic drug monitoring of tricyclics are beyond the scope of this article. The Clinical Pharmacogenetics Implementation Consortium (CPIC) of the National Institutes of Health's Pharmacogenomics Research Network develops peer-reviewed gene–drug guidelines that are published and updated periodically at <http://www.pharmgkb.org> based on new developments in the field.

FOCUSED LITERATURE REVIEW

A systematic literature review focused on *CYP2D6* and *CYP2C19* genotyping and its relevance to gene-based dosing of tricyclics was conducted (see **Supplementary Data** online). This guideline was developed based on interpretation of the literature by the authors and experts in the field.

GENES: *CYP2D6* AND *CYP2C19*

CYP2D6 background

The *CYP2D6* gene is highly polymorphic.¹¹ More than 100 known allelic variants and subvariants have been identified, and there are substantial ethnic differences in observed allele frequencies (**Supplementary Data** online). The most commonly reported

Table 1 Assignment of likely phenotypes based on diplotypes

Likely phenotype	Activity score ^a	Genotypes	Examples of diplotypes
Assignment of CYP2D6 phenotype			
Ultrarapid metabolizer (~1–2% of patients) ^b	>2.0	An individual carrying duplications of functional alleles	(*1/*1)xN, (*1/*2)xN, (*2/*2)xN ^c
Extensive metabolizer (~77–92% of patients)	1.0–2.0 ^d	An individual carrying two functional alleles or two reduced function alleles or one functional and nonfunctional allele or one functional and reduced function allele	*1/*1, *1/*2, *2/*2, *1/*9, *1/*41, *41/*41, *1/*5, *1/*4
Intermediate metabolizer (~2–11% of patients)	0.5	An individual carrying one reduced function and one nonfunctional allele	*4/*41, *5/*9, *4/*10
Poor metabolizers (~5–10% of patients)	0	An individual carrying only nonfunctional alleles	*4/*4, *3/*4, *5/*5, *5/*6
Assignment of CYP2C19 phenotype			
Ultrarapid metabolizer (~5–30% of patients) ^e		An individual carrying two gain-of-function alleles or one functional allele and one gain-of-function allele	*17/*17, *1/*17
Extensive metabolizer (~35–50% of patients)		An individual carrying two functional alleles	*1/*1
Intermediate metabolizer (~18–45% of patients)		An individual carrying one functional allele and one loss-of-function allele	*1/*2, *1/*3
Poor metabolizers (~2–15% of patients)		An individual carrying two loss-of-function alleles	*2/*2, *2/*3, *3/*3

^aSee **Supplementary Data** for additional information about CYP2D6 activity score and its limitations. ^bCYP2D6 metabolizer status frequencies are based on data from Caucasians and may differ from other ethnicities. ^cxN represents the number of CYP2D6 gene copies. ^dPatients with an activity score of 1.0 may be classified as intermediate metabolizers by some reference laboratories. ^eCYP2C19 metabolizer status frequencies are based on average multiethnic frequency.

alleles are categorized into functional groups as follows: functional (e.g., CYP2D6*1 and *2), reduced function (e.g., CYP2D6*9, *10, and *41), and nonfunctional (e.g., CYP2D6*3–*6).^{11,12} Because CYP2D6 is subject to deletions or duplications, most clinical laboratories also report copy number. Deletions are indicated by the CYP2D6*5 allele, and gene duplications are denoted by an “xN” following the allele (e.g., CYP2D6*1xN, where xN represents the number of CYP2D6 gene copies).

CYP2C19 background

Similar to CYP2D6, the CYP2C19 gene is highly polymorphic; more than 30 known allelic variants and subvariants have been identified.¹³ Although there are ethnic differences in allele frequencies (**Supplementary Data** online), the majority of patients carry a CYP2C19*1, *2, or *17 allele.¹³ CYP2C19*1 is the wild-type allele encoding a fully functional enzyme, and CYP2C19*2 is the most common loss-of-function allele. Multiple CYP2C19 loss-of-function alleles have been identified (e.g., CYP2C19*3–*8), but their allele frequencies are <1%, with the exception of CYP2C19*3, which has a frequency of 2–15% in Asians.¹³

The CYP2C19*17 allele results in enhanced gene transcription purportedly leading to increased metabolic activity.¹⁴ However, the clinical importance of the CYP2C19*17 allele is a matter of debate. Some studies indicate that CYP2C19*17 enhances clopidogrel response and increases the probability of therapeutic failure for proton pump inhibitors or antidepressants due to altered drug plasma concentrations, but there are conflicting clinical data.^{13–19}

Genetic test interpretation

Clinical laboratories usually test for the more frequently observed CYP2D6 and CYP2C19 genetic variants and translate the results

into star-allele (*) nomenclature. Each star-allele, or haplotype, is defined by a specific combination of single-nucleotide polymorphisms and/or other genetic variants within the gene locus of either CYP2D6 or CYP2C19.^{11,13} Genetic test results are reported as the summary of inherited maternal and paternal star-alleles referred to as a diplotype (e.g., CYP2D6*1/*2 and CYP2C19*1/*1). See **Supplementary Data** online for the more frequently observed alleles and their functional status.

Scoring systems have been developed in an attempt to provide a uniform approach to quantitate the predicted functional status of CYP2D6 alleles as follows: 1 for functional, 0.5 for reduced function, and 0 for nonfunctional alleles (**Supplementary Data** online).^{11,12} The activity value for each allele of the diplotype is totaled to provide a CYP2D6 activity score. If CYP2D6 gene duplications are detected, the activity value of the duplicated allele is multiplied by the number of duplications present before calculating the activity score. The CYP2D6 activity score is used to assign phenotype in this guideline as follows: patients with an activity score of 0 are classified as poor metabolizers, those with a score of 0.5 are intermediate metabolizers, those with a score from 1.0 to 2.0 are extensive metabolizers, and those with a score >2.0 are classified as ultrarapid metabolizers (**Table 1**, **Supplementary Data** online). Extensive metabolizers are considered to have normal CYP2D6 enzyme activity.

There is a lack of consensus with regard to whether patients with a CYP2D6 activity score of 1.0 should be assigned an extensive or intermediate phenotype.¹¹ Pharmacokinetic data suggest that patients with an activity score of 1.0 have a higher CYP2D6 metabolic capacity as compared with patients with an activity score of 0.5 but less CYP2D6 enzyme activity as compared with patients with an activity score of 2.0.¹² Patients with one functional and one nonfunctional CYP2D6 allele do not have

significantly different nortriptyline plasma concentrations as compared with patients with two functional *CYP2D6* alleles,²⁰ although another study reported conflicting data.⁷ Herein, we classified patients with a *CYP2D6* activity score of 1.0 as extensive metabolizers, which is analogous to the CPIC guideline for codeine.¹¹

The predicted *CYP2C19* phenotype based on the diplotype (Table 1 and Supplementary Data online) is consistent with the CPIC guideline for clopidogrel.¹³ Patients with two functional alleles are categorized as extensive metabolizers, which is considered normal *CYP2C19* enzyme activity. Individuals carrying one or two loss-of-function alleles are considered intermediate and poor metabolizers, respectively. Patients with two gain-of-function alleles are classified as ultrarapid metabolizers. The predicted phenotype for a patient carrying the *CYP2C19*17* gain-of-function allele in combination with a loss-of-function allele is a matter of debate. Limited data suggest that *CYP2C19*17* may not compensate for the *CYP2C19*2* allele.^{15,21}

Reference laboratories use varying methods to assign phenotypes. Before pharmacotherapy modifications are made based on this guideline, it is advisable to determine a patient's phenotype as described above.

Available genetic test options

CYP2D6 and *CYP2C19* genotyping is available from several reference laboratories (see Supplementary Data online and <http://www.pharmgkb.org>).

Incidental findings

Independent of drug metabolism and response, there are currently no diseases or conditions that have been convincingly linked to variants in the *CYP2D6* or *CYP2C19* genes.^{11,13} Reports describing an association between *CYP2D6* ultrarapid metabolizers and suicidality, and *CYP2C19* polymorphisms and depressive symptoms are available.^{22–24} These associations are poorly understood and may be explained by alterations in either drug or endogenous substrate metabolism.

DRUGS: AMITRIPTYLINE AND NORTRIPTYLINE

Background

Tricyclics are mixed serotonin and norepinephrine reuptake inhibitors used to treat several disease states including depression, obsessive–compulsive disorder, and neuropathic pain in addition to migraine prophylaxis. The tricyclics have similar but distinct chemical structures referred to as tertiary and secondary amines. The pharmacological properties of the tertiary and secondary amines differ, with tertiary amines having a more pronounced serotonergic effect and secondary amines having a greater noradrenergic effect (Supplementary Data online).^{25,26} The tertiary amines (e.g., amitriptyline) are mainly metabolized by *CYP2C19* to desmethyl metabolites (Figure 1), also referred to as secondary amines (e.g., nortriptyline). It should be noted that the desmethyl metabolites, nortriptyline as well as desipramine, are antidepressant drugs themselves with distinct clinical features that differ from the parent drugs

amitriptyline and imipramine. Both the tertiary and secondary amines are metabolized by *CYP2D6* to less active hydroxy metabolites (Figure 1, Supplementary Data online). *CYP2C19* impacts the ratio of tertiary to secondary amine plasma concentrations but may have less influence on overall drug clearance than *CYP2D6*.²⁷ However, *CYP2C19* metabolism may modulate antidepressant activity and side effects through the pharmacological actions of the tertiary amines. Serotonin reuptake inhibition is expected to be more pronounced in *CYP2C19* poor metabolizers due to the decreased conversion of tertiary to secondary amines.²⁶

Patients may be predisposed to treatment failure or adverse effects due to polymorphisms in *CYP2D6* and *CYP2C19* altering drug clearance or the ratio of parent drug to metabolites, respectively. Tricyclics are associated with multiple adverse effects, which can cause patients to fail therapy. Common adverse effects include anticholinergic, central nervous system, and cardiac effects. Tertiary and secondary amines along with their metabolites have unique side-effect profiles as detailed in Supplementary Data online.

Both amitriptyline and nortriptyline are used as model drugs for this guideline because the majority of pharmacogenomic studies have focused on these two drugs. However, the results of these studies may apply to other tricyclics because these drugs have comparable pharmacokinetic properties.^{4,8} Tricyclics are well absorbed from the gastrointestinal tract, and the average extent of first-pass metabolism is ~50%, although the average first-pass metabolism of doxepin may be closer to 70%.⁴ The clearance of tricyclics is mostly a linear process, but saturation of the hydroxylation pathway may occur at higher plasma concentrations for certain tricyclics, including imipramine and desipramine.^{4,28} In addition, extrapolated dose adjustments based on metabolizer status are similar across the tricyclic class.⁸ Because some studies investigating the influence of *CYP2D6* and/or *CYP2C19* genotype/phenotype on the pharmacokinetics of tricyclics used a single dose, it should be noted that tricyclic metabolism is thought to be similar after single and multiple dosing.⁵

Linking genetic variability to variability in drug-related phenotypes

Psychiatric disorders such as depression have a 30–50% failure rate with initial treatment, which may, in part, be attributed to adverse effects or altered plasma concentrations.^{9,29} There is substantial evidence linking *CYP2D6* and *CYP2C19* genotypes to phenotypic variability in tricyclic side-effect and pharmacokinetic profiles. Modifying pharmacotherapy for patients

Figure 1 Major metabolic pathway of amitriptyline and nortriptyline.

who have *CYP2D6* or *CYP2C19* genomic variants that affect drug efficacy and safety could potentially improve clinical outcomes and reduce the failure rate of initial treatment. The application of a grading system to the evidence linking *CYP2D6* and *CYP2C19* genotypic variations to phenotypic variability in response to amitriptyline or nortriptyline indicates a high quality of evidence in the majority of cases (**Supplementary Data** online). This body of evidence, rather than randomized clinical

trials, provides the basis for amitriptyline and nortriptyline dosing recommendations in **Tables 2** and **3**. Because the tricyclics have comparable pharmacokinetic properties, it may be reasonable to apply this guideline to other tricyclics, including clomipramine, desipramine, doxepin, imipramine, and trimipramine (**Supplementary Data** online), with the acknowledgment that there are fewer data supporting dose adjustments for these drugs than for amitriptyline or nortriptyline.

Table 2 Dosing recommendations for amitriptyline and nortriptyline based on CYP2D6 phenotype

Phenotype	Implication	Therapeutic recommendation	Classification of recommendation ^a
CYP2D6 ultrarapid metabolizer	Increased metabolism of tricyclics to less active compounds as compared with extensive metabolizers	Avoid tricyclic use due to potential lack of efficacy. Consider alternative drug not metabolized by CYP2D6	Strong
	Lower plasma concentrations will increase probability of pharmacotherapy failure	If a tricyclic is warranted, consider increasing the starting dose. ^b Use therapeutic drug monitoring to guide dose adjustments	
CYP2D6 extensive metabolizer	Normal metabolism of tricyclics	Initiate therapy with recommended starting dose ^b	Strong
CYP2D6 intermediate metabolizer	Reduced metabolism of tricyclics to less active compounds as compared with extensive metabolizers	Consider 25% reduction of recommended starting dose. ^b Use therapeutic drug monitoring to guide dose adjustments	Moderate
	Higher plasma concentrations will increase the probability of side effects		
CYP2D6 poor metabolizer	Greatly reduced metabolism of tricyclics to less active compounds as compared with extensive metabolizers	Avoid tricyclic use due to potential for side effects. Consider alternative drug not metabolized by CYP2D6	Strong
	Higher plasma concentrations will increase the probability of side effects	If a tricyclic is warranted, consider a 50% reduction of recommended starting dose. ^b Use therapeutic drug monitoring to guide dose adjustments	

If *CYP2C19* genotyping results are also available, see **Table 3** for *CYP2C19*-based dosing recommendations along with **Supplementary Data** online. Dosing recommendations apply only to higher initial doses of amitriptyline or nortriptyline for treatment of conditions such as depression. See “Other Considerations” for dosing recommendations for conditions in which lower initial doses are used, such as neuropathic pain. For the dosing guidelines for clomipramine, desipramine, doxepin, imipramine, and trimipramine, see **Supplementary Data** online.

^aThe rating scheme for the recommendation classification is described in the **Supplementary Data** online. ^bPatients may receive an initial low dose of tricyclics, which is then increased over several days to the recommended steady-state dose. The starting dose in this guideline refers to the recommended steady-state dose.

Table 3 Dosing recommendations of amitriptyline based on CYP2C19 phenotype

Phenotype	Implication	Therapeutic recommendation	Classification of recommendation ^a
CYP2C19 ultrarapid metabolizer	Increased metabolism of amitriptyline as compared with extensive metabolizers	Consider alternative drug not metabolized by CYP2C19	Optional
		If a tricyclic is warranted, use therapeutic drug monitoring to guide dose adjustments	
CYP2C19 extensive metabolizer	Normal metabolism of amitriptyline	Initiate therapy with recommended starting dose ^b	Strong
CYP2C19 intermediate metabolizer	Reduced metabolism of amitriptyline as compared with extensive metabolizers	Initiate therapy with recommended starting dose ^b	Strong
CYP2C19 poor metabolizer	Greatly reduced metabolism of amitriptyline as compared with extensive metabolizers	Consider a 50% reduction of recommended starting dose. ^b Use therapeutic drug monitoring to guide dose adjustments	Moderate
	Higher plasma concentrations of amitriptyline will increase the probability of side effects		

If *CYP2D6* genotyping results are also available, see **Table 2** for *CYP2D6*-based dosing recommendations along with **Supplementary Data** online. Dosing recommendations apply only to higher initial doses of amitriptyline for treatment of conditions such as depression. See “Other Considerations” for dosing recommendations for conditions at which lower initial doses are used, such as neuropathic pain. For dosing guidelines for clomipramine, doxepin, imipramine, and trimipramine, see **Supplementary Data** online.

^aThe rating scheme for the recommendation classification is described in the **Supplementary Data** online. ^bPatients may receive an initial low dose of tricyclics, which is then increased over several days to the recommended steady-state dose. The starting dose in this guideline refers to the recommended steady-state dose.

Therapeutic recommendations

CYP2D6 dosing recommendations. For neuropathic pain treatment, in which lower initial doses of tricyclics are used, gene-based dosing recommendations are found in the “Other Considerations” section. **Table 2** summarizes the gene-based dosing recommendations for amitriptyline and nortriptyline based on CYP2D6 phenotype for situations requiring a higher initial dose, such as depression treatment. The recommended starting dose of amitriptyline or nortriptyline does not need adjustment based on genotype for CYP2D6 extensive metabolizers. A 25% reduction of the recommended dose may be considered for CYP2D6 intermediate metabolizers.³⁰ Because patients with a CYP2D6 activity score of 1.0 are inconsistently categorized as intermediate or extensive metabolizers in the literature, these are difficult to evaluate, resulting in a moderate recommendation classification.

CYP2D6 ultrarapid metabolizers have a higher probability of failing amitriptyline or nortriptyline pharmacotherapy due to subtherapeutic plasma concentrations, and therefore alternative agents are preferred. There are documented cases of CYP2D6 ultrarapid metabolizers receiving large doses of nortriptyline to achieve therapeutic concentrations.¹⁰ However, very high plasma concentrations of the nortriptyline hydroxy metabolite were present, which may increase the risk for cardiotoxicity. If a tricyclic is warranted, there are insufficient data in the literature to calculate a starting dose for a patient with CYP2D6 ultrarapid metabolizer status, and therapeutic drug monitoring is strongly recommended. Adverse effects are more likely in CYP2D6 poor metabolizers due to elevated tricyclic plasma concentrations,³¹ therefore, alternative agents are preferred. If a tricyclic is warranted, consider a 50% reduction of the usual dose; therapeutic drug monitoring is strongly recommended.

CYP2C19 dosing recommendations. Dosing recommendations for neuropathic pain treatment with amitriptyline are discussed in the “Other Considerations” section. **Table 3** summarizes the gene-based dosing recommendations for CYP2C19 and amitriptyline when higher initial starting doses are warranted. The usual starting dose of amitriptyline may be used in CYP2C19 extensive and intermediate metabolizers. Although CYP2C19 intermediate metabolizers would be expected to have a modest increase in the ratio of amitriptyline to nortriptyline plasma concentrations, the evidence does not indicate that CYP2C19 intermediate metabolizers should receive an alternative dose.

Patients taking amitriptyline who are CYP2C19 ultrarapid metabolizers may be at risk of having altered plasma concentrations or adverse events. Although the *CYP2C19*17* allele did not alter the sum of amitriptyline plus nortriptyline plasma concentrations, it was associated with higher nortriptyline plasma concentrations, possibly increasing the risk of adverse events.¹⁵ For patients taking amitriptyline, extrapolated pharmacokinetic data suggest that CYP2C19 ultrarapid metabolizers may need a dose increase.⁸ Due to the need for further studies investigating the clinical importance of the *CYP2C19*17* allele and the possibility of altered tricyclic concentrations, we recommend consideration of an alternative tricyclic or other drug

not affected by CYP2C19. Because the clinical importance of *CYP2C19*17* is currently poorly understood, this recommendation is classified as optional. If amitriptyline is administered to a CYP2C19 ultrarapid metabolizer, therapeutic drug monitoring is recommended.

CYP2C19 poor metabolizers are expected to have a greater ratio of amitriptyline to nortriptyline plasma concentrations.³² The elevated amitriptyline plasma concentrations may increase the chance of a patient experiencing side effects. Consider a 50% reduction of the usual amitriptyline starting dose along with therapeutic drug monitoring.⁸

CYP2D6 and CYP2C19 combined dosing recommendations. Although specific combinations of *CYP2D6* and *CYP2C19* alleles are likely to result in additive effects on the pharmacokinetic properties of tricyclics, little information is available on how to adjust initial doses based on combined genotype information. Patients carrying at least one *CYP2D6* nonfunctional allele and two *CYP2C19* functional alleles had an increased risk of experiencing side effects when administered amitriptyline, whereas patients with at least one *CYP2C19* loss-of-function allele and two *CYP2D6* functional alleles had a low risk of experiencing side effects.^{10,33} Because there is only sparse clinical evidence for an additive effect of *CYP2D6* and *CYP2C19* on tricyclic dosing, the recommendations are classified as optional (**Supplementary Data** online).

Other considerations

Gene-based dosing recommendations for neuropathic pain treatment. Amitriptyline is often used at lower dosages (e.g., 0.1 mg/kg/day in pediatric patients) for treatment of neuropathic pain than when used for depressive disorders.^{2,3} Because of the lower dosage, it is less likely that CYP2D6 or CYP2C19 poor or intermediate metabolizers will experience adverse effects due to supratherapeutic plasma concentrations of amitriptyline.³⁴ Therefore, we recommend no dose modifications for poor or intermediate metabolizers when prescribed amitriptyline at a lower dose for treatment of neuropathic pain, but these patients should be monitored closely for side effects. If larger doses of amitriptyline are warranted, we recommend following the gene-based dosing guidelines presented in **Tables 2** and **3**.

Providing dose recommendations for CYP2C19 ultrarapid metabolizers when amitriptyline is prescribed at lower doses for neuropathic pain treatment is difficult. On the basis of predicted and observed pharmacokinetic data, CYP2D6 ultrarapid metabolizers are at risk of failing amitriptyline therapy for neuropathic pain, and thus alternative agents such as gabapentin should be considered.³⁵ Although little information is available on how to adjust initial amitriptyline doses based on combined *CYP2D6* and *CYP2C19* genetic results when treating neuropathic pain, caution should be used when patients have a combination of poor or ultrarapid phenotypes (e.g., a CYP2D6 poor metabolizer also having CYP2C19 ultrarapid or poor metabolism).

Consideration of drug interactions and patient characteristics. Patients treated for psychiatric disorders often require multiple

medications, which can influence tricyclic plasma concentrations, side effects, and therapeutic failure.⁴ For example, patients taking amitriptyline in combination with a potent CYP2D6 inhibitor, such as fluoxetine, may have dramatic increases in plasma concentrations.³⁶ It has been suggested that patients taking strong CYP2D6 inhibitors should be treated similarly to CYP2D6 poor metabolizers.¹¹ In addition, patients with increased age, liver disease, and reduced renal function may require reduced doses of tricyclics.^{4,37,38} Drug–drug interactions along with patient characteristics should be considered in addition to the gene-based dosing recommendations presented herein.

Minor metabolic pathways of tricyclics. Other cytochrome P450 enzymes, including CYP3A4 and CYP1A2, metabolize tricyclics to a lesser extent.^{4,34,39,40} There is currently no strong evidence supporting gene-based dosing recommendations for other cytochrome P450 enzymes that metabolize tricyclics.

Potential benefits and risks for the patient

For patients who have existing *CYP2D6* and/or *CYP2C19* genotyping test results, the potential benefit is identifying those patients who are at an elevated risk of experiencing side effects or therapeutic failure. For those patients, dose adjustments can be made or an alternative agent selected. A limitation inherent to most commercially available genotyping tests is that rare or *de novo* variants are not detected. In addition, some alleles are not well characterized, resulting in uncertainty when predicting the phenotype for some genetic test results. Genotyping is reliable when performed in qualified reference laboratories, but, as with any laboratory test, an error can occur. Any errors in genotyping or phenotype prediction, along with the presence of a rare genomic variant not tested for, could potentially affect the patient lifelong.

Caveats: appropriate use and/or potential misuse of genetic tests

The application of genotype-based dosing is most appropriate when initiating therapy with a tricyclic. Obtaining a pharmacogenetic test after months of drug therapy may be less helpful in some instances, given that the drug dose may have already been adjusted based on plasma concentrations, response, or side effects. Similar to all diagnostic tests, genetic tests are one of several pieces of clinical information that should be considered before initiating drug therapy.

DISCLAIMER

CPIC guidelines reflect expert consensus based on clinical evidence and peer-reviewed literature available at the time they are written; they are intended only to assist clinicians in decision making and to identify questions for further research. New evidence may have emerged since the time a guideline was submitted for publication. Guidelines are limited in scope and are not applicable to interventions or diseases not specifically identified. Guidelines do not account for all individual variations among patients and cannot be considered inclusive of all proper methods of care or

exclusive of other treatments. It remains the responsibility of the health-care provider to determine the best course of treatment for a patient. Adherence to any guideline is voluntary, with the ultimate determination regarding its application to be made solely by the clinician and the patient. CPIC assumes no responsibility for any injury to persons or damage to persons or property arising out of or related to any use of CPIC's guidelines, or for any errors or omissions.
